IERG 5350 Assignment 3: Value Function Approximation in RL

2020-2021 Term 1, IERG 5350: Reinforcement Learning. Department of Information Engineering, The Chinese University of Hong Kong. Course Instructor: Professor ZHOU Bolei. Assignment author: PENG Zhenghao, SUN Hao, ZHAN Xiaohang.

Student Name	Student ID
Wang Wanli	1155160517

Welecome to the assignment 3 of our RL course.

You need to go through this self-contained notebook, which contains many TODOs in part of the cells and has special `[TODO]` signs. You need to finish all TODOs. Some of them may be easy such as uncommenting a line, some of them may be difficult such as implementing a function. You can find them by searching the `[TODO]` symbol. However, we suggest you to go through the notebook step by step, which would give you a better understanding of the content.

You are encouraged to add more code on extra cells at the end of the each section to investigate the problems you think interesting. At the end of the file, we left a place for you to optionaly write comments (Yes, please give us rewards so we can keep improving the assignment!).

Please report any code bugs to us via github issue.

We will cover the following knowledege in this assignment:

1. The n-step TD control algorithm
2. Linear function as value approximator
3. Feature construction
4. Neural network based function approximation
5. The basic usage of Pytorch

In the first section of notebook, we build a basic RL pipeline. In the second section, we implement the linear function as approximator and also introduces feature construction technique. In the third section, we implement a simple neural network simply using Numpy package.

**Before starting, make sure you have installed the following packages:

1. Python 3
2. Jupyter Notebook
3. Gym
4. gym[atari], install via `pip install 'gym[atari]'`
5. Numpy
6. Pytorch, please refer to official website [https://pytorch.org (https://pytorch.org)](https://pytorch.org) for installation guide

Section 1: Basic Reinforcement Learning Pipeline

(5 / 100 points)

In this section, we will prepare several functions for evaulation, training RL algorithms. We will also build an `AbstractTrainer` class used as a general framework which left blanks for different function approximation methods.

```

Section 2: Linear function approximation

In this section, we implement a simple linear function whose input is the state (or the processed state) and output is the state-action values.

First, we implement a `LinearTrainer` class which implements (1). Linear function approximation and (2). n-step semi-gradient method to update the linear function.

Then we further implement a `LinearTrainerWithFeatureConstruction` class which processs the input state and provide polynomial features which increase the utility of linear function approximation.

We refer the Chapter 9.4 (linear method), 9.5 (feature construction), and 10.2 (n-step semi-gradient method) of the RL textbook to you.

In this section, we leverage the n-step semi-gradient. What is the "correct value" of an action and state in one-step case? We consider it is $r_t + \gamma Q(s_{t+1}, a_{t+1})$ and thus lead to the TD error $TD = r_t + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)$. In n-step case, the target value of Q is:

$$Q(s_t, a_t) = \sum_{i=t}^{t+n-1} \gamma^{i-t} r_i + \gamma^n Q(s_{t+n}, a_{t+n})$$

We follow the pipeline depicted in Chapter 10.2 (page 247) of the textbook to implement this logic. Note that notation of the time step of reward is different in this assignment and in the textbook. In textbook, the reward R_{t+1} is the reward when apply action a_t to the environment at state s_t. In the equation above the r_t has exactly the same meaning. In the code below, we store the states, actions and rewards to a list during training. You need to make sure the indices of these list, like the `tau` in `actions[tau]` has the correct meaning.

After computing the target Q value, we need to derive the gradient to update the parameters. Consider a loss function, the Mean Square Error between the target Q value and the output Q value:

$$\text{loss} = \frac{1}{2}[\sum_{i=t}^{t+n-1} \gamma^{i-t} r_i + \gamma^n Q(s_{t+n}, a_{t+n}) - Q(s_t, a_t)]^2$$

Compute the gradient of Loss with respect to the Q function:

$$\frac{d\text{loss}}{dQ} = -(\sum_{i=t}^{t+n-1} \gamma^{i-t} r_i + \gamma^n Q(s_{t+n}, a_{t+n}) - Q(s_t, a_t))$$

According to the chain rule, the gradient of the loss w.r.t. the parameter (W) is:

$$\frac{d\text{loss}}{dW} = -(\sum_{i=t}^{t+n-1} \gamma^{i-t} r_i + \gamma^n Q(s_{t+n}, a_{t+n}) - Q(s_t, a_t))\frac{dQ}{dW}$$

To minimize the loss, we only need to descent the gradient:

$$W = W - lr\frac{d\text{loss}}{dW}$$

wherein lr is the learning rate. Therefore, in conclusion the update rule of parameters is:

$$W = W + lr(\sum_{i=t}^{t+n-1} \gamma^{i-t} r_i + \gamma^n Q(s_{t+n}, a_{t+n}) - Q(s_t, a_t))\frac{dQ}{dW}$$

In the following codes, we denote $G = \sum_{i=t}^{t+n-1} \gamma^{i-t} r_i + \gamma^n Q(s_{t+n}, a_{t+n})$ and will compute dQ/dW according to the form of the approximator.

Section 2.1: Basics

(30 / 100 points)

We want to approximate the state-action values. That is, the expected return when applying action a_t in state s_t. Linear methods approximate state-action value function by the inner product between a parameter matatrix W and the input state vector s:

$$v(s, W) = W^T s$$

Note that $W \in \mathbb{R}^{(O,A)}$ and $s \in \mathbb{R}^{(O,1)}$, wherein O is the observation (state) dimensions, namely the `self.obs_dim` in trainer and A is the action dimension, namely the `self.act_dim` in trainer. Each action corresponding to one state-action values $Q(s, a)$.

Note that you should finish this section **purely by Numpy without calling any other packages**.

(9.0s,+0.9s)    Iteration 10000, current mean episode reward is 9.84.
```

In [81]:

```
# Run this cell without modification

# You should see a pop up window which display the movement of the cart and pole.
print("Average episode reward for your linear agent in CartPole-v0: ",
      linear_trainer.evaluate(1, render=True))
```

```
Average episode reward for your linear agent in CartPole-v0:  10.0
```

You will notice that the linear trainer only has 8 trainable parameters and its performance is quiet bad. In the following section, we will expand the size of parameters and introduce more features as the input to the system so that the system can learn more complex value function.

Section 2.2: Linear Model with Feature Construction

(15 / 100 points)

Section 3: Multi-layer Perceptron as the approximiator

In this section, you are required to implement a single agent MLP using purely Numpy package. The differences between MLP and linear function are (1). MLP has a hidden layer which increase its representation capacity (2). MLP can leverage activation function after the output of each layer which introduce not linearity.

Consider a MLP with one hidden layer containing 100 neurons and activation function `f()` . We call the layer that accepts the state as input and output the activation **hidden layer**, and the layer that accepts the activation as input and produces the values **output layer**. The activation of the hidden layer is:

$$a(s_t) = f(W_h^T s_t)$$

obvious the activation is a 100-length vector. The output values is:

$$Q(s_t) = f(W_o^T a(s_t))$$

wherein W_h, W_o are the parameters of hidden layer and output layer, respectively. In this section we do not add activation function and hence $f(x) = x$.

Moreover, we also introduce the gradient clipping mechanism. In on-policy learning, the norm of gradient is prone to vary drastically, since the output of Q function is unbounded and it can be as large as possible, which leads to exploding gradient issue. Gradient clipping is used to bound the norm of gradient while keeps the direction of gradient vector unchanged. Concretely, the formulation of gradient clipping is:

$$g_{clipped} = g_{original} \frac{c}{\max(c, \mathrm{norm}(g))}$$

wherein c is a hyperparameter which is `config["clip_norm"]` in our implementation. Gradient clipping bounds the gradient norm to c if the norm of original gradient is greater than c. You need to implement this mechanism in function `apply_gradient` in the following cell.

In [85]:

```
# Solve the TODOs and remove `pass`

# Build the algorithm-specify config.
mlp_trainer_config = merge_config(dict(
    parameter_std=0.01,

Average episode reward for your MLP agent with gradient clipping in CartPole-v0:
200.0
```

Interesting right? The gradient clipping technique makes the training converge much faster!

Section 4: Implement Deep Q Learning in Pytorch

(50 / 100 points)

In this section, you will get familiar with the basic logic of pytorch, which lay the ground for further learning. We will implement a MLP similar to the one in Section 3 using Pytorch, a powerful Deep Learning framework. Before start, you need to make sure using `pip install torch` to install it.

If you are not familiar with Pytorch, we suggest you to go through pytorch official quickstart tutorials:

1. [quickstart (https://pytorch.org/tutorials/beginner/deep_learning_60min_blitz.html)](https://pytorch.org/tutorials/beginner/deep_learning_60min_blitz.html)
2. [tutorial on RL (https://pytorch.org/tutorials/intermediate/reinforcement_q_learning.html)](https://pytorch.org/tutorials/intermediate/reinforcement_q_learning.html)

Different from the algorithm in Section 3, we will implement Deep Q Network (DQN) in this section. The main differences are concluded as following:

DQN requires an experience replay memory to store the transitions. A replay memory is implemented in the following `ExperienceReplayMemory` class. It can contain a certain amount of transitions: `(s_t, a_t, r_t, s_t+1, done_t)`. When the memory is full, the earliest transition is discarded to store the latest one.

The introduction of replay memory increase the sample efficiency (since each transition might be used multiple times) when solving complex task, though you may find it learn slowly in this assignment since the CartPole-v0 is a relatively easy environment.

DQN is an off-policy algorithm and has difference when computing TD error, compared to Sarsa. In Sarsa, the TD error is computed as:

$$(r_t + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t))$$

wherein the next action a_{t+1} is the one the policy selects. However, in traditional Q learning, it assume the next action is the one that maximizes the action values and use this assumption to compute the TD:

$$(r_t + \gamma \max_{a_{t+1}} Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t))$$

DQN has make delayed update target network, which is another difference even compared to the traditional Q learning. DQN maintains another neural network called target network that has identical structure of the Q network. After a certain amount of steps has been taken, the target network copies the parameters of the Q network to itself. Normally, the update of target network is much less frequent than the update of the Q network. The Q network is updated in each step.

The reason to leverage the target network is to stabilize the estimation of TD error. In DQN, the TD error is evaluated as:

$$(r_t + \gamma \max_{a_{t+1}} Q^{target}(s_{t+1}, a_{t+1}) - Q(s_t, a_t))$$

The Q values of next state is estimated by the target network, not the Q network that is updating. This mechanism can reduce the variance of gradient because the estimation of Q values of next states is not influenced by the update of the Q network.

In the engineering aspect, the differences between `DQNTrainer` and the previous `MLPTrainer` are:

1. DQN uses pytorch model to serve as the approximator. So we need to rewrite the `initialize_parameter` function to build the pytorch model. Also the `train` function is changed since the gradient optimization is conducted by pytorch, therefore we need to write the pytorch pipeline in `train`.
2. DQN has replay memory. So we need to initialize it, feed data into it and take the transitions out.

3. Thank to the replay memory and pytorch, DQN can be updated in a batch. So you need to carefully compute the Q target via matrix computation.
4. We use Adam optimizer to conduct the gradient optimization. You need to get familiar with how to compute the loss and conduct backward propagation

Conclusion and Discussion

In this assignment, we learn how to build several function approximation algorithm, how to implement basic gradient descent methods and how to use pytorch.

It's OK to leave the following cells empty. In the next markdown cell, you can write whatever you like. Like the suggestion on the course, the confusing problems in the assignments, and so on.

If you want to do more investigation, feel free to open new cells via `Esc + B` after the next cells and write codes in it, so that you can reuse some result in this notebook. Remember to write sufficient comments and documents to let others know what you are doing.

Following the submission instruction in the assignment to submit your assignment to our staff. Thank you!
